Why statistical/iterative methods for CT?

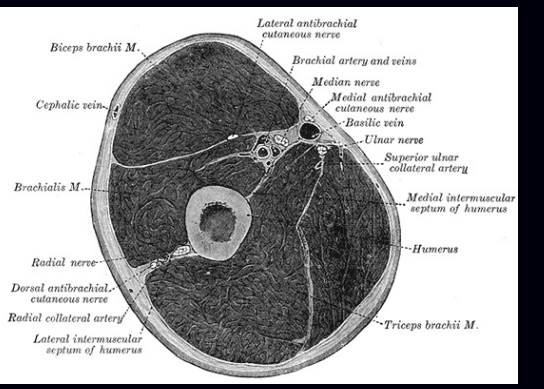
- Accurate physics models
  - X-ray spectrum, beam-hardening, scatter, ...
    $\Longrightarrow$ reduced artifacts? quantitative CT?
  - X-ray detector spatial response, focal spot size, ...
    $\Longrightarrow$ improved spatial resolution?
  - detector spectral response (*e.g.*, photon-counting detectors)
    $\Longrightarrow$ improved contrast?

- Nonstandard geometries
  - transaxial truncation (wide patients)
  - long-object problem in helical CT
  - irregular sampling in "next-generation" geometries
  - coarse angular sampling in image-guidance applications
  - limited angular range (tomosynthesis)
  - "missing" data, *e.g.*, bad pixels in flat-panel systems

- Appropriate models of (data dependent) measurement statistics
  - weighting reduces influence of photon-starved rays (*cf.* FBP)
    $\Longrightarrow$ reducing image noise or X-ray dose

and more...

- Object constraints / priors
  - nonnegativity
  - object support
  - piecewise smoothness
  - object sparsity (*e.g.*, angiography)
  - sparsity in some basis
  - motion models
  - dynamic models
  - ...



Henry Gray, Anatomy of the Human Body, 1918, Fig. 413.

These constraints may help reduce image artifacts or noise or dose.

Disadvantages?

- Computation time (super computer)
- Must reconstruct entire FOV
- Complexity of models and software
- Algorithm nonlinearities
  - Difficult to analyze resolution/noise properties (*cf.* FBP)
  - Tuning parameters
  - Challenging to characterize performance / assess image quality

"Iterative" vs "Statistical"

- Traditional *successive substitutions* iterations
  - *e.g.*, Joseph and Spital (JCAT, 1978) bone correction
  - usually only one or two "iterations"
  - not statistical

- Algebraic reconstruction methods
  - Given sinogram data $\boldsymbol{y}$ and system model $\boldsymbol{A}$, reconstruct object $\boldsymbol{x}$ by "solving" $\boldsymbol{y} = \boldsymbol{A}\boldsymbol{x}$
  - ART, SIRT, SART, ...
  - iterative, but typically not statistical $\Longrightarrow$ limited (if any) dose reduction
  - Iterative filtered back-projection (FBP):

$$\boldsymbol{x}^{(n+1)} = \boldsymbol{x}^{(n)} + \underbrace{\alpha}_{\text{step size}} \text{FBP}(\underbrace{\boldsymbol{y}}_{\text{data}} - \underbrace{\boldsymbol{A}\boldsymbol{x}^{(n)}}_{\text{forward project}})$$

- Statistical reconstruction methods now come in several flavors:
  - Image domain
  - Sinogram domain
  - Fully statistical (both)
  - Hybrid methods (*e.g.*, AIR, SPIE 7961-18, 2011, Bruder *et al.*)

  Examine these in more detail next to consider *dose*.

"Statistical" methods: Image domain

- Denoising methods

$$\text{sinogram } \boldsymbol{y} \rightarrow \boxed{\text{FBP}} \rightarrow \text{noisy reconstruction } \tilde{\boldsymbol{x}} \rightarrow \boxed{\text{iterative denoiser}} \rightarrow \text{final image } \hat{\boldsymbol{x}}$$

  - Relatively fast, even if iterative
  - Remarkable advances in denoising methods in last decade

Zhu & Milanfar, T-IP, Dec. 2010, using "steering kernel regression" (SKR) method

Challenges:

  - Typically assume *white noise*
  - Streaks in low-dose FBP appear like edges (highly correlated noise)

- Image denoising methods “guided by data statistics”

  - Image-domain methods are fast (thus very practical)
  - ASIR? IRIS? ...
  - The technical details are often a mystery...

Challenges:
  - FBP often does not use all data efficiently (*e.g.*, Parker weighting)
  - Low-dose CT statistics most naturally expressed in sinogram domain

Several studies of potential dose reduction with image-domain methods:
  - Hara *et al.*, AJR 193(3) 2009, 32-65 % dose reduction
  - Silva *et al.*, AJR 194(1) 2010, 50-65 % dose reduction
  - Leipsic *et al.*, AJR 195(3) 2010, 27 % dose reduction
  - ...

"Statistical" methods: Sinogram domain

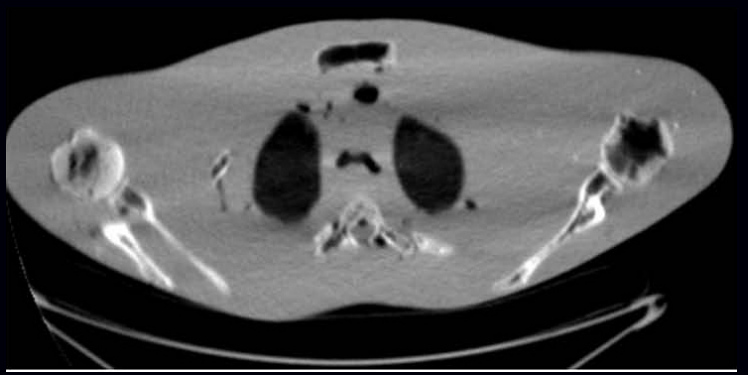
- Sinogram restoration methods

$$\underset{\boldsymbol{y}}{\text{noisy sinogram}} \rightarrow \boxed{\text{adaptive or iterative denoiser}} \rightarrow \underset{\hat{\boldsymbol{y}}}{\text{cleaned sinogram}} \rightarrow \boxed{\text{FBP}} \rightarrow \underset{\hat{\boldsymbol{x}}}{\text{final image}}$$

  - Adaptive: J. Hsieh, Med. Phys., 1998; Kachelrieß, Med. Phys., 2001, ...
  - Iterative: P. La Riviere, IEEE T-MI, 2000, 2005, 2006, 2008, ...
  - Relatively fast even if iterative

  Challenges:
  - Limited denoising without resolution loss $\Longrightarrow$ modest dose reduction?
  - Difficult to "preserve edges" in sinograms

FBP, 10 mA



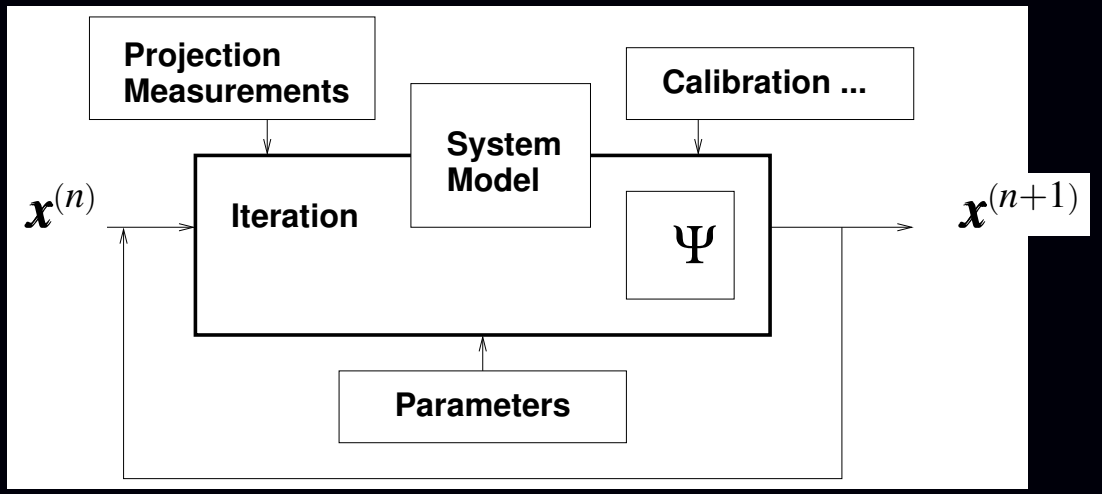
FBP from denoised sinogram

Wang *et al.*, T-MI, Oct. 2006, using PWLS-GS on sinogram

"Fully" (?) statistical image reconstruction

- Object model
- Physics/system model
- Statistical model
- Cost function (log-likelihood + regularization)
- Iterative algorithm for minimization

"Find the image $\hat{x}$ that best fits the sinogram data y according to the physics model, the statistical model and prior information about the object"



- Repeatedly revisiting the sinogram data can use measurement statistics fully
- Repeatedly updating the image can exploit object properties
- ∴ greatest potential dose reduction, but repetition is expensive...

Example comparison

Thin-slice FBP

ASIR

Statistical

(Same sinogram, so all at same dose)

MBIR example: Routine chest CT

Helical chest CT study with dose = 0.09 mSv.
Typical CXR effective dose is about 0.06 mSv. Source: Health Physics Society.

Five Choices for Statistical Image Reconstruction

1. Object model
2. System physical model
3. Measurement statistical model
4. Cost function: data-mismatch and regularization
5. Algorithm / initialization

No perfect choices - one can critique all approaches!

Historically these choices are often left implicit in publications,
but being explicit facilitates reproducibility.

Next: overview of each choice, focusing on how they may affect dose.

Choice 1. Object Parameterization

Finite measurements: $\{y_i\}_{i=1}^{M}$. Continuous object: $f(\vec{r}) = \mu(\vec{r})$.

"All models are wrong but some models are useful."

Linear *series expansion* approach. Represent $f(\vec{r})$ by $\boldsymbol{x} = (x_1, \ldots, x_N)$ where

$$f(\vec{r}) \approx \tilde{f}(\vec{r}) = \sum_{j=1}^{N} x_j b_j(\vec{r}) \quad \leftarrow \quad \text{"basis functions"}$$

Reconstruction problem becomes "discrete-discrete:" estimate $\boldsymbol{x}$ from $\boldsymbol{y}$

Numerous basis functions in literature. Two primary contenders:

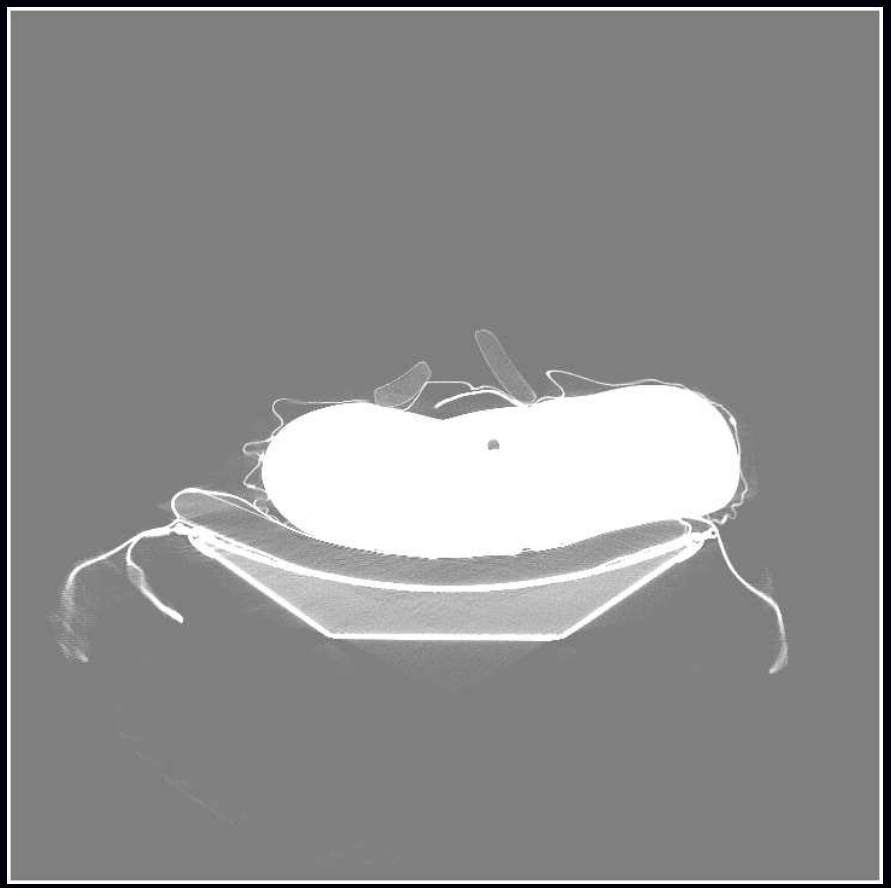
- voxels
- blobs (Kaiser-Bessel functions)
  - \+ Blobs are approximately band-limited (reduced aliasing?)
  - – Blobs have larger footprints, increasing computation.

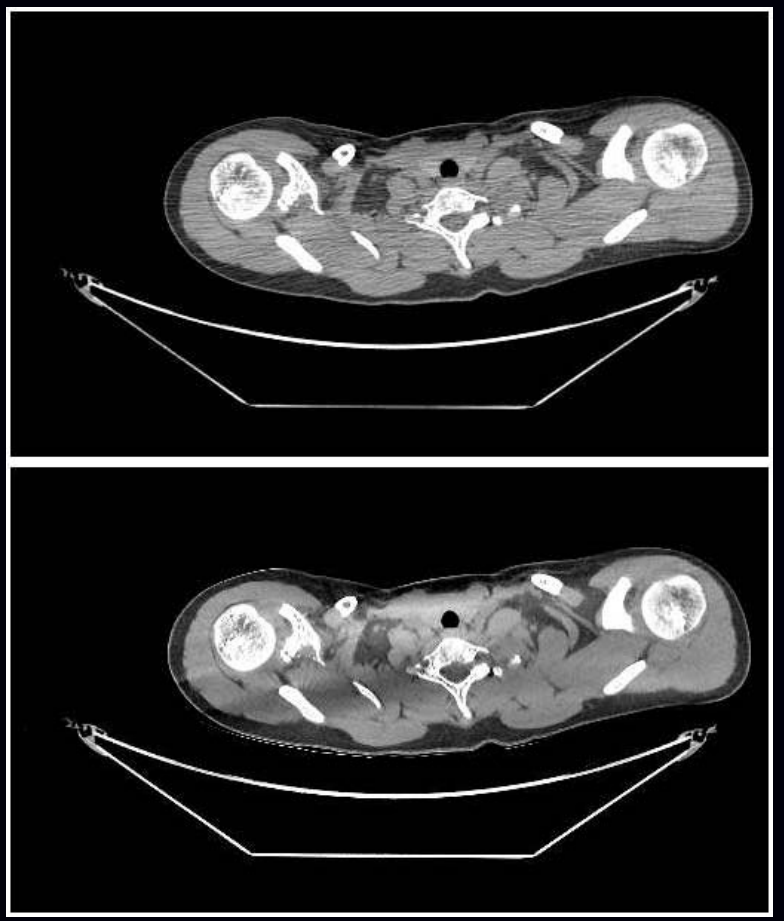
Open question: how small should the voxels be?

One practical compromise: wide FOV coarse-grid reconstruction followed by fine-grid refinement over ROI, *e.g.*, Ziegler *et al.*, Med. Phys., Apr. 2008

Global reconstruction: An inconvenient truth

70-cm FOV reconstruction

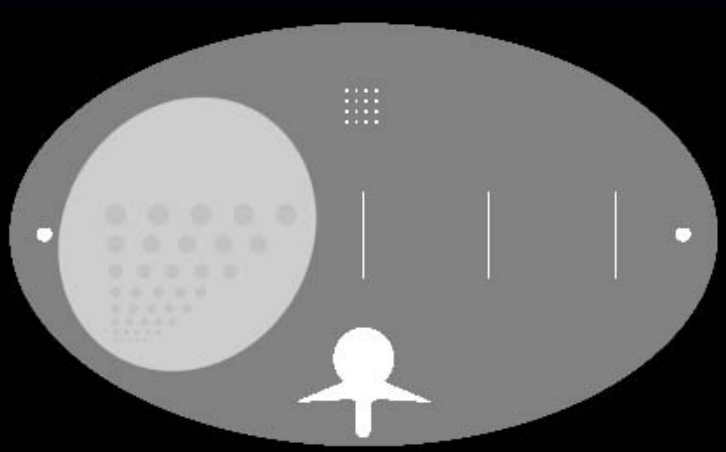




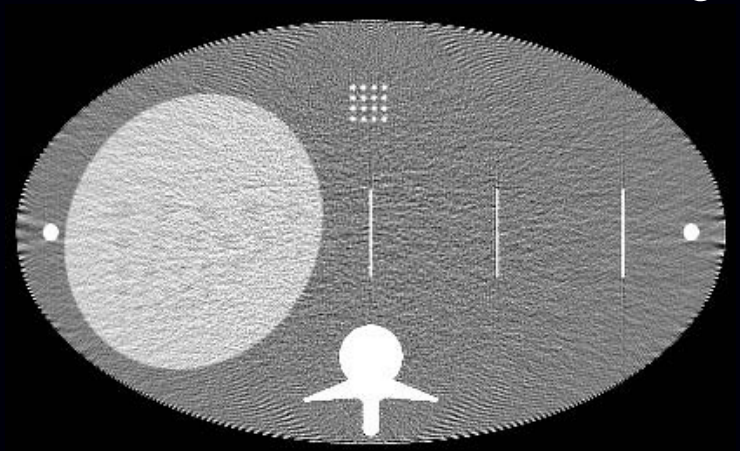
Thibault *et al.*, Fully3D, 2007

For a statistical approach to interior tomography, see Xu *et al.*, IEEE T-MI, May 2011.

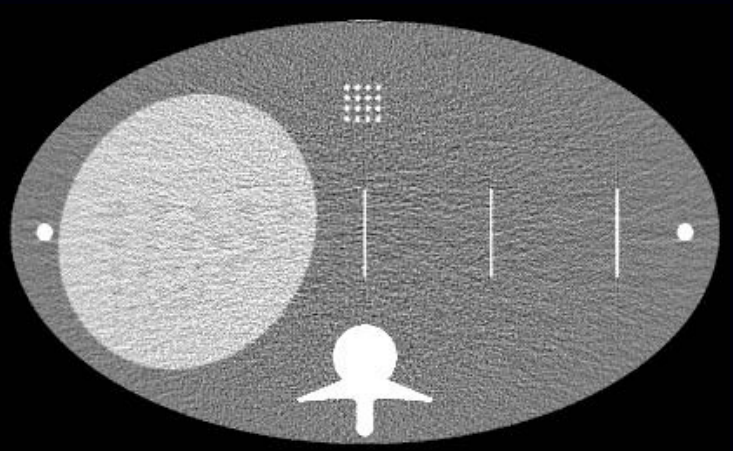
Voxel size matters?



digital phantom



512^2 grid



1024^2 grid

Unregularized OS reconstructions. Zbijewski & Beekman, PMB, Jan. 2004

Choice 2. System model / Physics model

- scan geometry
- source intensity I_0
  - spatial variations (air scan)
  - intensity fluctuations
- resolution effects
  - finite detector size / detector spatial response
  - finite X-ray spot size / anode angulation
  - detector afterglow / gantry rotation
- spectral effects
  - X-ray source spectrum
  - bowtie filters
  - detector spectra response
- scatter
- ...

Challenges / trade-offs

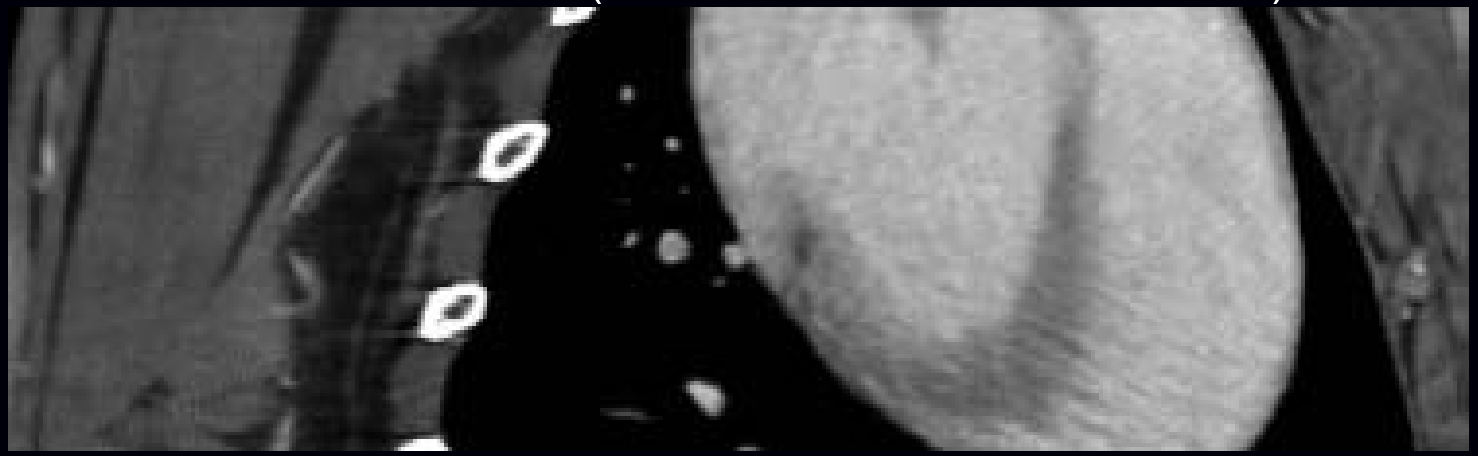
- computation time
- accuracy/artifacts/resolution/contrast
- dose?

Detector size modeling matters

From (De Man and Basu, PMB, Jun. 2004) MLTR of rabbit heart

Ray-driven (idealized point detector)

Distance-driven (models finite detector width)



Forward- / Back-projector "Pairs"

Typically iterative algorithms require two key steps.

- forward projection (image domain to projection domain):

$$\bar{\boldsymbol{y}} = \boldsymbol{A}\boldsymbol{x}, \qquad \bar{y}_i = \sum_{j=1}^{N} a_{ij} x_j = [\boldsymbol{A}\boldsymbol{x}]_i$$

- backprojection (projection domain to image domain):

$$\boldsymbol{z} = \boldsymbol{A}'\boldsymbol{y}, \qquad z_j = \sum_{i=1}^{M} a_{ij} y_i$$

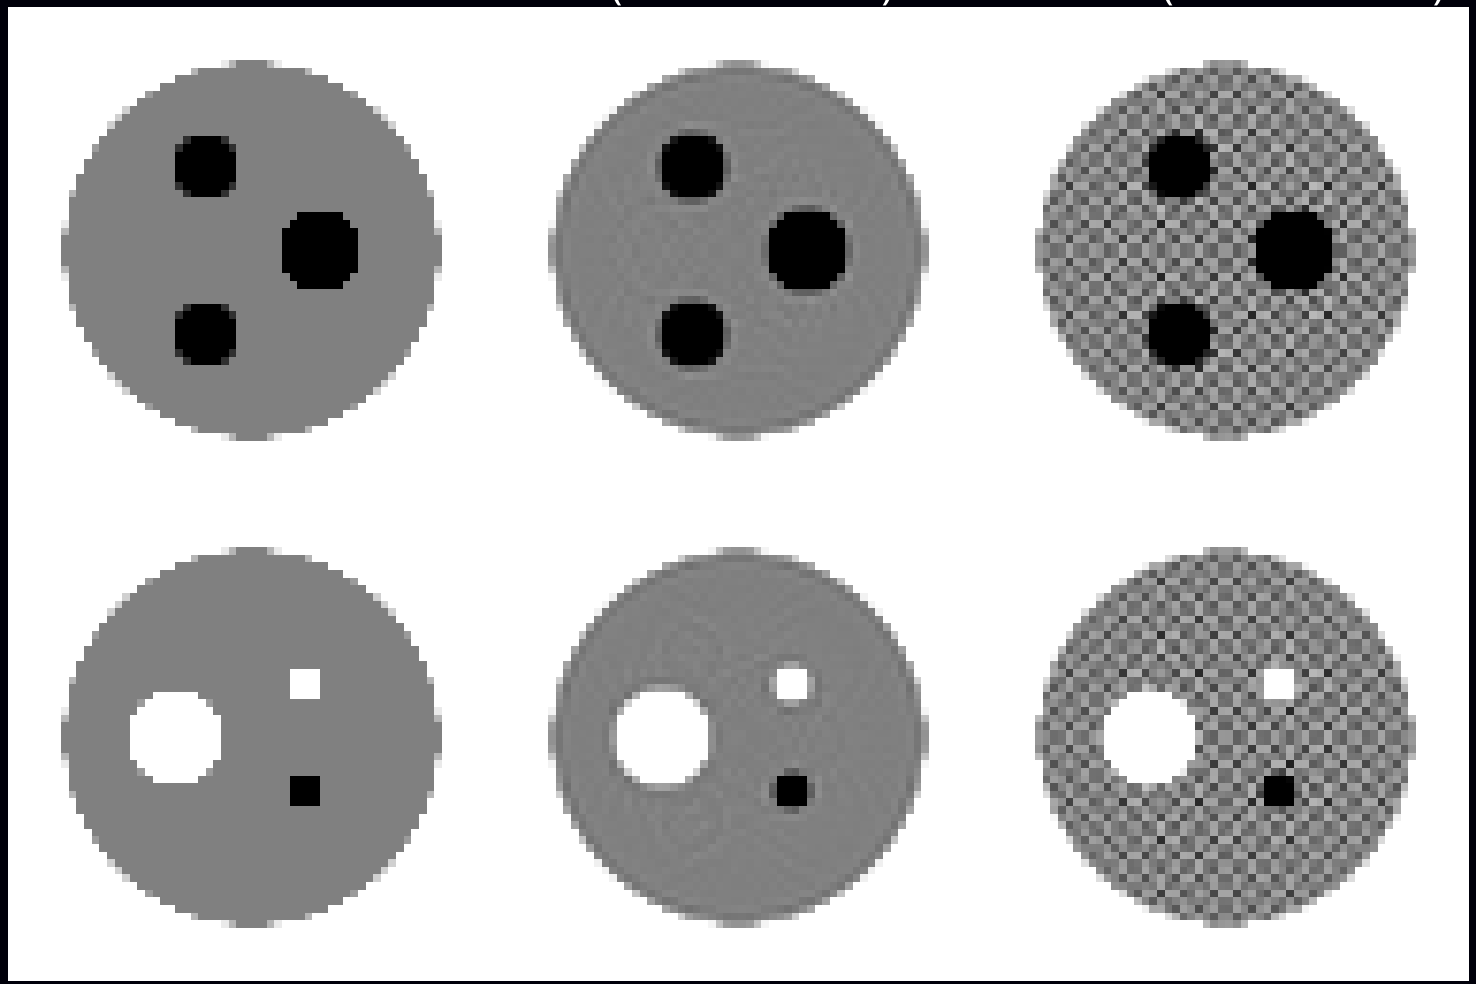
The term "forward/backprojection pair" often refers to some implicit choices for the object basis and the system model.

Sometimes $\boldsymbol{A}'\boldsymbol{y}$ is implemented as $\boldsymbol{B}\boldsymbol{y}$ for some "backprojector" $\boldsymbol{B} \neq \boldsymbol{A}'$. Especially in SPECT and sometimes in PET and CT.

Least-squares solutions (for example):

$$\hat{\boldsymbol{x}} = \arg\min_{\boldsymbol{x}} \|\boldsymbol{y} - \boldsymbol{A}\boldsymbol{x}\|^2 = \left[\boldsymbol{A}'\boldsymbol{A}\right]^{-1} \boldsymbol{A}'\boldsymbol{y} \neq \left[\boldsymbol{B}\boldsymbol{A}\right]^{-1} \boldsymbol{B}\boldsymbol{y}$$

Mismatched Backprojector $B \neq A'$



cf. SPECT/PET reconstruction – usually unregularized

Choice 3. Statistical Model

The physical model describes measurement mean,
e.g., for a monoenergetic X-ray source and ignoring scatter etc.:

$$\bar{I}_i = I_0 \, \mathrm{e}^{-\sum_{j=1}^{N} a_{ij} x_j} .$$

The raw noisy measurements $\{I_i\}$ are distributed around those means.
Statistical reconstruction methods require a model for that distribution.

Challenges / Trade offs: using more accurate statistical models

- *may* lead to less noisy images
- may incur additional computation
- may involve higher algorithm complexity.

CT measurement statistics are very complicated, particularly at low doses.

- incident photon flux variations (Poisson)
- X-ray photon absorption/scattering (Bernoulli)
- energy-dependent light production in scintillator (?)
- shot noise in photodiodes (Poisson?)
- electronic noise in readout electronics (Gaussian?)
  Whiting, SPIE 4682, 2002; Lasio *et al.*, PMB, 2007; Massoumzadeh *et al.*, PMB 2009
- Inaccessibility of raw sinogram data

To log() or not to log() – That is the question

Models for "raw" data I_i (before logarithm)

- compound Poisson (complicated) Whiting, SPIE 4682, 2002; Elbakri & Fessler, SPIE 5032, 2003; Lasio *et al.*, PMB, Apr. 2007
- Poisson + Gaussian (photon variability and electronic readout noise):

$$I_i \sim \text{Poisson}\{\bar{I}_i\} + \text{N}\left(0, \sigma^2\right)$$

  Snyder *et al.*, JOSAA, May 1993 & Feb. 1995 .
- Shifted Poisson approximation (matches first two moments):

$$\tilde{I}_i \triangleq \left[I_i + \sigma^2\right]_+ \sim \text{Poisson}\left\{\bar{I}_i + \sigma^2\right\}$$

  Yavuz & Fessler, MIA, Dec. 1998
- Ordinary Poisson (ignore electronic noise):

$$I_i \sim \text{Poisson}\{\bar{I}_i\}$$

  Rockmore and Macovski, TNS, Jun. 1977; Lange and Carson, JCAT, Apr. 1984
- Photon-counting detectors would simplify statistical modeling

All are somewhat complicated by the nonlinearity of the physics: $\bar{I}_i = \mathrm{e}^{-[\boldsymbol{A}\boldsymbol{x}]_i}$

After taking the log()

Taking the log leads to a simpler linear model (ignoring beam hardening):

$$y_i \triangleq -\log\left(\frac{I_i}{I_0}\right) \approx [\boldsymbol{A}\boldsymbol{x}]_i + \varepsilon_i$$

Drawbacks:

- Undefined if $I_i \leq 0$ (due to electronic noise); bad for very low-dose scans
- It is *biased* (by Jensen's inequality): $\mathsf{E}[y_i] \geq -\log(\bar{I}_i/I_0) = [\boldsymbol{A}\boldsymbol{x}]_i$
- Exact distribution of log-domain noise ε_i is intractable.

Practical approach: assume Gaussian noise model: $\varepsilon_i \sim \mathsf{N}\left(0, \sigma_i^2\right)$

Options for modeling noise variance $\sigma_i^2 = \mathsf{Var}\{\varepsilon_i\}$

- consider both Poisson and Gaussian noise effects: $\sigma_i^2 = \frac{\bar{I}_i + \sigma^2}{\bar{I}_i^2}$
  (Thibault *et al.*, SPIE 6065, 2006)
- consider just Poisson effect: $\sigma_i^2 = \frac{1}{\bar{I}_i}$ (Sauer & Bouman, T-SP, Feb. 1993)
- pretend it is white noise: $\sigma_i^2 = \sigma_0^2$
- ignore noise altogether and "solve" $\boldsymbol{y} = \boldsymbol{A}\boldsymbol{x}$

Whether using pre-log data is better than post-log data is an open question, especially for very low-dose scans (*cf.* experience with PET rod scans).

Choice 4. Cost Functions

Components:

- 4.1 *Data-mismatch* term
- 4.2 *Regularization* term (and regularization parameter β)
- 4.3 *Constraints* (*e.g.*, nonnegativity: minor effect on noise / dose)

Reconstruct image $\hat{\boldsymbol{x}}$ by finding minimizer of a cost function:

$$\hat{\boldsymbol{x}} \triangleq \underbrace{\underset{\boldsymbol{x} \geq \boldsymbol{0}}{\arg\min}}_{\text{Constraints}} \Psi(\boldsymbol{x})$$

$$\Psi(\boldsymbol{x}) = \text{DataMismatch}(\boldsymbol{y}, \boldsymbol{A}\boldsymbol{x}) + \beta \, \text{Regularizer}(\boldsymbol{x})$$

Forcing too much "data fit" alone would give noisy images.

Equivalent to a Bayesian MAP (maximum *a posteriori*) estimator.

Distinguishes "statistical methods" from "algebraic methods" for "$\boldsymbol{y} = \boldsymbol{A}\boldsymbol{x}$."

Such optimization-based formulation appears to be key to low-dose CT.
Theoretically optimizes bias-variance trade-off (Eldar, IEEE T-SP, Jul. 2004).

Choice 4.1: Data-Mismatch Term

Standard choice is the negative log-likelihood of statistical model:

$$\text{DataMismatch} = -L(\boldsymbol{x};\boldsymbol{y}) = -\log \mathrm{p}(\boldsymbol{y}|\boldsymbol{x}) = \sum_{i=1}^{M} -\log \mathrm{p}(y_i|\boldsymbol{x})\,.$$

- For pre-log data $\boldsymbol{I}$ with shifted Poisson model:

$$-L(\boldsymbol{x};\boldsymbol{I}) = \sum_{i=1}^{M} \left(\bar{I}_i + \sigma^2\right) - \left[I_i + \sigma^2\right]_+ \log\left(\bar{I}_i + \sigma^2\right), \qquad \bar{I}_i = I_0\, \mathrm{e}^{-[\boldsymbol{A}\boldsymbol{x}]_i}$$

  This can be non-convex if $\sigma^2 > 0$;
  it is convex if we ignore electronic noise $\sigma^2 = 0$. Trade-off ...

- For post-log data $\boldsymbol{y}$ with Gaussian model:

$$-L(\boldsymbol{x};\boldsymbol{y}) = \sum_{i=1}^{M} w_i \frac{1}{2}(y_i - [\boldsymbol{A}\boldsymbol{x}]_i)^2 = \frac{1}{2}(\boldsymbol{y} - \boldsymbol{A}\boldsymbol{x})'\boldsymbol{W}(\boldsymbol{y} - \boldsymbol{A}\boldsymbol{x}), \qquad w_i = 1/\sigma_i^2$$

  This is a kind of (data-based) weighted least squares (WLS).
  It is always convex in $\boldsymbol{x}$. Quadratic functions are “easy” to minimize.

- ...
- Effect on dose is related to statistical model accuracy

Choice 4.2: Regularization

How to control noise due to ill-conditioning in tomography?
Perhaps the most important factor influencing "how low (dose) can we go"

Noise-control methods (used in clinical PET reconstruction today):

- Stop an unregularized algorithm before convergence
- Over-iterate an unregularized algorithm then post-filter

Other possible "simple" solutions:

- Modify the raw data (pre-filter / denoise)
- Filter between iterations
- ...

Appeal:

- simple / familiar
- filter parameters have intuitive units (*e.g.*, FWHM), unlike a regularization parameter β
- Changing a post-filter does not require re-iterating, unlike changing a regularization parameter β

Regularization options

Options for regularizer $\mathsf{R}(\boldsymbol{x})$ in increasing complexity:

- quadratic roughness
- convex, non-quadratic roughness
- non-convex roughness
- total variation
- convex sparsity
- non-convex sparsity

Challenges

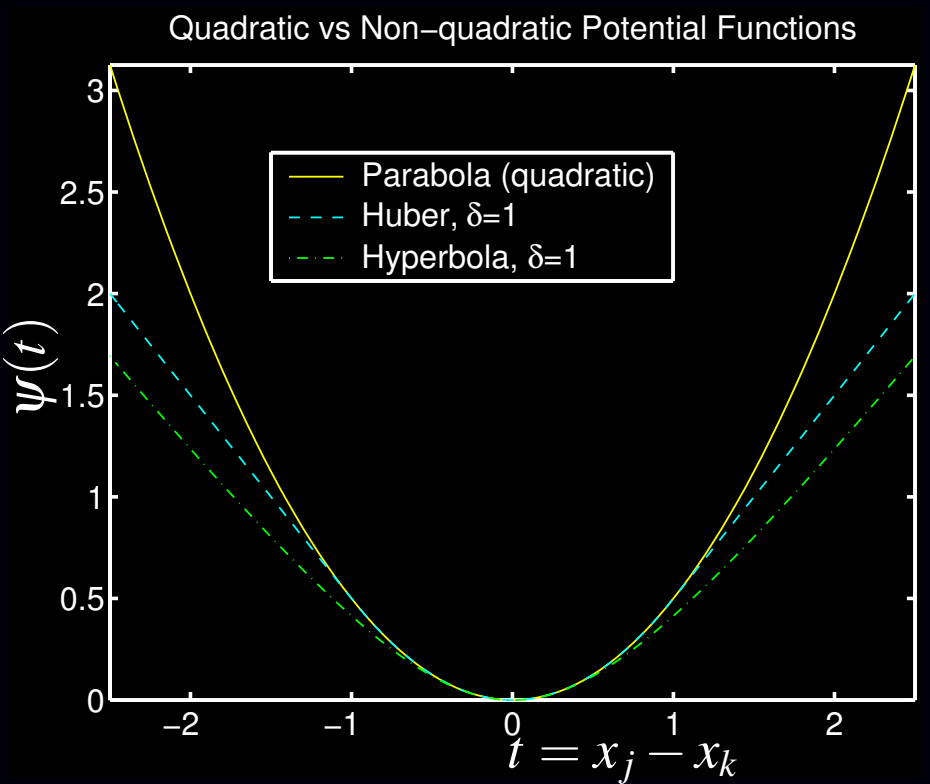
- Reducing noise without degrading spatial resolution
- Balancing regularization strength between and within slices
- Parameter selection
- Computational complexity (voxels have 26 immediate neighbors in 3D)
- Preserving “familiar” noise texture
- Optimizing clinical task performance

Many open questions...
Which regularization method can enable the lowest-dose scans?

Roughness Penalty Functions

$$\mathrm{R}(\boldsymbol{x}) = \sum_{j=1}^{N} \frac{1}{2} \sum_{k \in \mathcal{N}_j} \psi(x_j - x_k)$$

- $\mathcal{N}_j \triangleq$ *neighborhood* of jth pixel
  (*e.g.*, left, right, up, down in 2D; 26 neighbors in 3D)
- ψ called the *potential function*



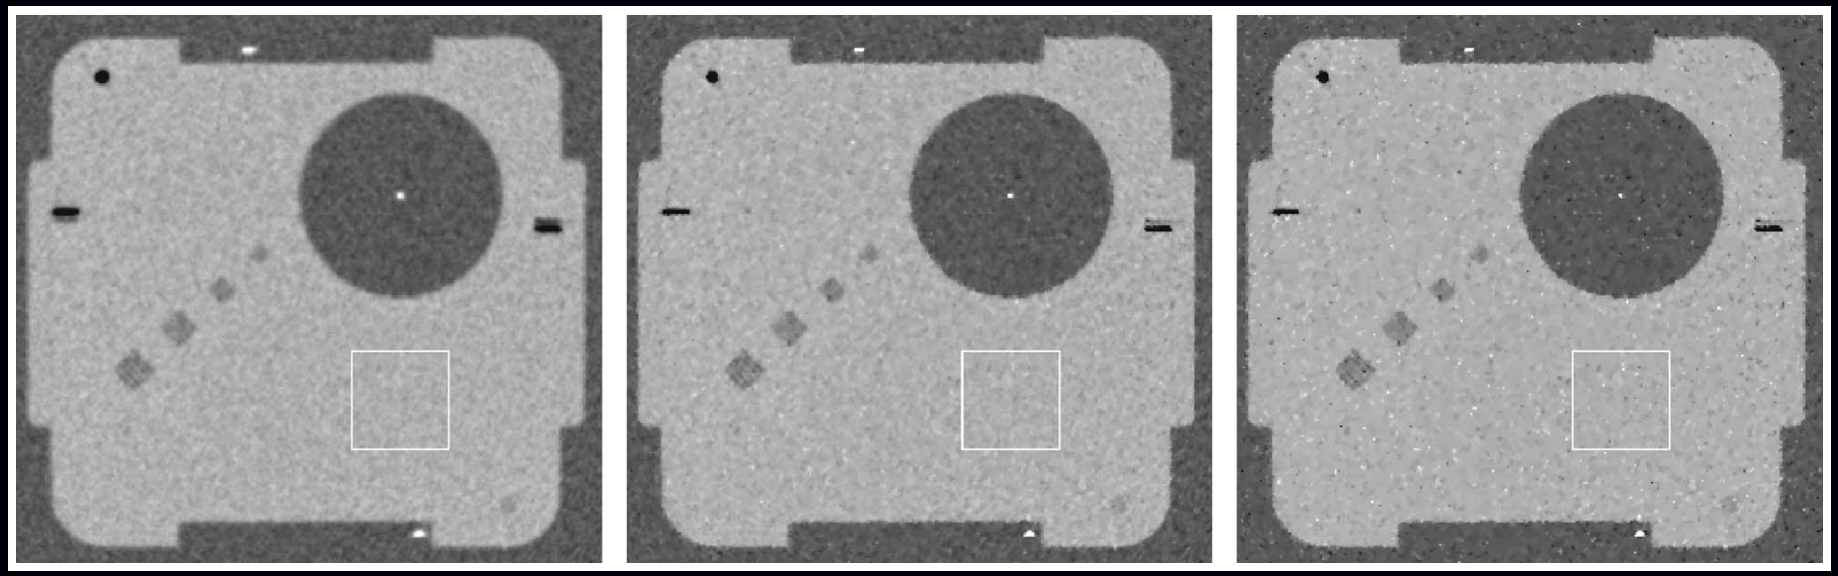
quadratic: $\psi(t) = t^2$
hyperbola: $\psi(t) = \sqrt{1 + (t/\delta)^2}$
(edge preservation)

Regularization parameters: Dramatic effects on IQ

"q generalized gaussian" potential function with tuning parameters: β, δ, p, q:

$$\beta\,\psi(t) = \beta \frac{\frac{1}{2}|t|^p}{1 + |t/\delta|^{p-q}}.$$

(Thibault *et al.*, Med. Phys., Nov. 2007)



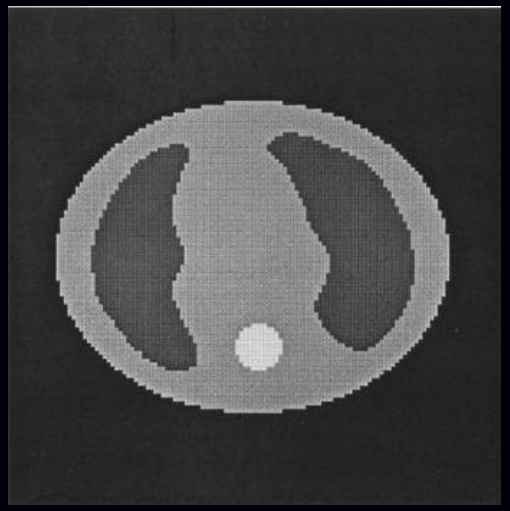
$p = q = 2$ $p = 2, q = 1.2, \delta = 10$ HU $p = q = 1.1$

noise:	11.1	10.9	10.8
(#lp/cm):	4.2	7.2	8.2

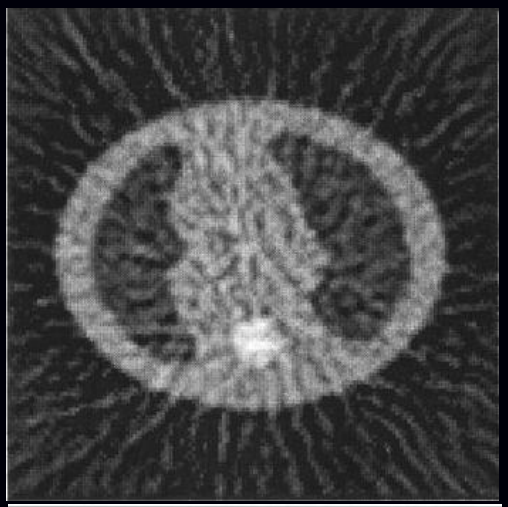
Which parameter choice enables the lowest dose scan?

Piecewise constant phantoms

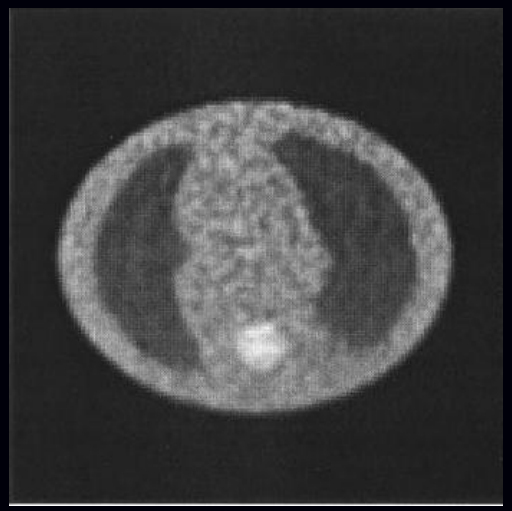
Phantom:



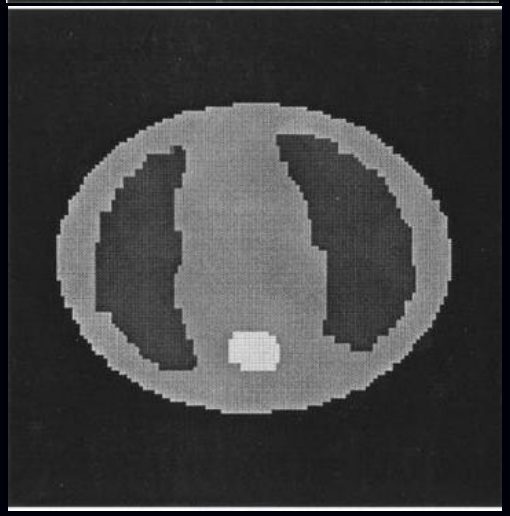
FBP:



MLEM:



MAP:



Lee *et al.*, IEEE T-NS, 2002, 300K counts
non-convex “broken parabola” potential function and deterministic annealing

Summary of statistical image reconstruction choices

1. Object parameterization
2. System physical model
3. Measurement statistical model
4. Cost function: data-mismatch / regularization / constraints

Reconstruction Method $\triangleq$ Models + Cost Function + Algorithm

5. Minimization algorithms: $\hat{\boldsymbol{x}} = \arg\min_{\boldsymbol{x}} \Psi(\boldsymbol{x})$

- The minimization algorithm has *no affect on image quality* / dose *if* we iterate "until convergence."
- For convergent algorithms, IQ determined entirely by cost function Ψ including the models within it.
- What happens we stop iterating "before convergence?" Affects dose? (Depends on algorithm and initial image...)
- Finding fast algorithms for arg min is key to ubiquitous low-dose CT. *e.g.*, alternating direction method of multipliers (ADMM) (Ramani & Fessler, IEEE T-MI, Mar. 2012)

Summary: Factors that affect dose reduction

In conjectured order from most important to least:

1. Regularizer
2. Statistical model / data-mismatch term
3. System model
4. Object model / non-negativity constraint
5. Iterative minimization algorithm

Other considerations that affect dose reduction

- 2D versus 3D reconstruction
  - 8 immediate neighbors in 2D versus 26 neighbors in 3D
  - transaxial versus axial relationships
- axial versus helical scans
- angular sampling: fine versus sparse
- dual energy / spectral CT versus single kVp

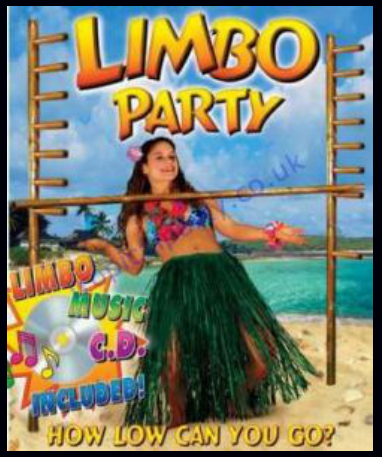
Recent dose figures for statistical image reconstruction

Yadava *et al.*, AAPM 2010, AAPM 2011
"average-probability-of-detection and average-detection-score of full dose FBP and 1/4th dose Veo [MBIR] are comparable."

Cohen *et al.*, AAPM 2011
[Phantom] "measurement differences between full dose FBP and 1/4th dose Veo were found to be statistically insignificant, indicating similar image quality."

Katsura *et al.*, Eur. Radiol. Aug. 2012 (hot off the press)
Compared FBP, ASIR, and "MBIR" (with no almost description);
concluded MBIR can work with "80% less radiation."

How low (dose) can you go?



http://laidoffinnyc.wordpress.com/2009/03/04/

- Depends on where you start
- Depends on many reconstruction method choices
- all of which affect IQ
  (which is harder to assess for nonlinear reconstruction methods)
- See next symposium...
- Conjecture: sub-mSv exams are achievable
