Memory Renaming: Fast, Early and Accurate Processing of Memory Communication

Gary S. Tyson[1] and Todd M. Austin[1]

Received April 6, 1999; revised May 18, 1999

As processors continue to exploit more instruction level parallelism, greater demands are placed on the performance of the memory system. In this paper, we introduce a novel modification of the processor pipeline called *memory renaming*. Memory renaming applies register access techniques to load and store instructions to speed the processing of memory traffic. The approach works by accurately predicting memory communication early in the pipeline and then re-mapping the communication to fast physical registers. This work extends previous studies of data value and dependence speculation. When memory renaming is added to the processor pipeline, renaming can be applied to 30–50% of all memory references, translating to an overall improvement in execution time of up to 14% for current pipeline configurations. As store forward delay times grow larger, renaming support can lead to performance improvements of as much as 42%. Furthermore, this improvement is seen across all memory segments—including the heap segment which has often been difficult to manage efficiently.

KEY WORDS: Memory; pipeline; prediction; renaming; speculation.

1. INTRODUCTION

For many programs, the performance of memory operations is often the greatest determinant of overall performance. To address the performance of memory, most modern microprocessors employ a variety of memory system optimizations to reduce the average latency of load instructions.

[1] The University of Michigan. E-mail: {tyson, taustin}@eecs.umich.edu.

Techniques such as caches, nonblocking memory access, out-of-order memory scheduling, and speculative store forwarding are now common in most high-end commercial offerings.

Two trends continue to propel the development of new memory system optimizations. First, the gap between processor and memory performance continues to grow with each new processor generation. While caches have been universally adopted to reduce the average memory access latency, designs will require faster storage close to the processor to continue scaling program performance. Caches, even single cycle, first level caches cannot satisfy this performance requirement due to their complex —and therefore slow—addressing mode.

Second, there is an ongoing trend towards exploitation of more instruction level parallelism through techniques such as superscalar issue and dynamic schedulers with large instruction windows. As window sizes grow, improvements in instruction issue rates (IPC) quickly fall off due to memory dependencies in the instruction issue window. Memory operations carry dependencies through memory—dependencies which are often a function of program computation (e.g., pointer addresses). As a result, mechanisms specific to loads and stores (e.g., the MOB in the Pentium Pro[1]) are required to resolve these memory dependencies later in the pipeline and enforce correct memory access semantics. A pair-wise comparison of the addresses of memory requests can enable some reordering of memory operations to different addresses. However, to date, the only effective solution for dealing with ambiguous (unresolved) memory addresses requires stalling all later loads until all earlier unknown addresses are resolved. This approach is overly conservative when loads stall waiting for the addresses of independent stores, resulting in increased load latency and reduced program performance.

Furthermore, if the scheduler logic cannot react to new addresses within the remainder of the address generation clock cycle, delay will be added between the time a store address is computed and the time a dependent load begins execution. Due to the complexity of memory scheduler logic, larger window sizes work to quickly increase this delay. To improve the overall performance of memory scheduling, techniques must be developed that provide accurate determination of memory dependencies early enough in the pipeline to keep memory scheduling off the critical path of program computation.

It is interesting to note that the register communication infrastructure already satisfies all of the earlier requirements for future memory communication designs: early and accurate determination of dependencies, and fast communication storage. Since register communication is described with fixed register identifiers, all register communication is specified very early in

the pipeline (at decode) and very accurately (precisely, in fact). In addition, register files are built with small memories that provide fast storage access. It is these valuable properties of register communication that makes this venerable communication infrastructure even more valuable today. Unfortunately, insufficient registers and the requirement that only unaliased data be inserted into registers forces many operands into memory. However, using speculation we can achieve the performance and convenience of register communication for many stores and loads.

We propose a technique called *memory renaming* that leverages the aspects of register communication to improve the performance of memory operations. Memory renaming achieves early and accurate description of memory dependencies by predicting store/load communication. These predictions allow the dynamic instruction scheduler to more accurately determine when loads should commence execution. Unlike previous work on address prediction, memory renaming does not identify the address used to transmit the value, instead, the approach identifies the store instruction responsible for writing the data. Once a stable dependence between a store and load is found, their future communication is mapped into the *value file*. The value file is small directly addressed register file that provides storage for fast speculative memory communication. Once renamed, memory communication is processed in the pipeline like register communication, reordering operations as necessary. The term memory renaming derives from a similar technique called register renaming,[2] where logical registers are remapped to physical storage based on register dependencies.

In this paper, we examine the characteristics of the memory reference stream and propose a novel architectural modification to the pipeline to enable speculative execution of load instructions early in the pipeline (before address calculation). By doing this, true dependencies can be accurately speculated, in particular those true dependencies supporting the complex address calculations used to access the program data. This will be shown to have a significant impact on overall performance (as much as 41% speedup for the experiments presented).

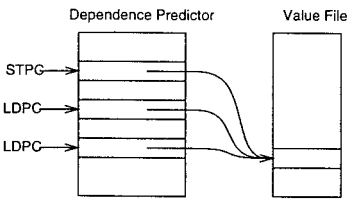
The remainder of this paper is organized as follows: Section 2 introduces the memory reordering approach to speculative load execution and evaluates the regularity of memory activity in order to identify the most successful strategy in executing loads speculatively. In Section 3, we show one possible integration of memory renaming into an out-of-order pipeline implementation. Section 4 provides performance analysis for a cycle-level simulation of the techniques. Section 5 examines alternate approaches to speculating load instructions and discusses more recent research extending our approach. In Section 6, we state conclusions and identify future research directions for this work.

2. RENAMING MEMORY OPERATIONS

Memory renaming is an extension to normal memory processing designed to speed up store/load communication. It works by predicting store/load communication early in the pipeline and then remapping the communication to physical registers. The approach achieves our goal of providing fast, accurate, and early determination of memory communication.

We achieve accurate and early identification of store/load dependencies through the use of a *memory dependence predictor*,[3] shown in Fig. 1a. A memory dependence predictor uses the program counter (PC) of a load to predict its sourcing store. Since the program counter of stores and loads are known from the first stage of the pipeline, we can initiate memory dependence prediction very early in the pipeline, early enough to not impact scheduling latency. The predictor achieves accuracy by leveraging the simple localities in the communication between stores and loads. Stores and loads that are predicted to communicate are bound to the same physical register in the *value file*. Accessing a value file entry can be performed (speculatively) without the effective address of the load or store instruction.

Our approach is speculative because the memory dependence predictor may mispredict the sourcing store of a load. To maintain correct operation in the presence of mispredictions, a mechanism must be in place to detect and recover from incorrect store forwarding. In our designs, we permit the effective address calculation and memory access operations to proceed as usual. The result of these operations are later used to validate the speculative value from the value file. If the data loaded from memory matches that from the value file, the speculation was successful and processing continues unfettered. If the values differ, then the state of the processor must be corrected.



a)

```
on stores:

  if (not in store/load cache)
    {
      allocate store/load cache entry for store
      allocate value file entry for store result
      point store/load cache entry to value file entry
    }
  deposit store result into value file and memory

on loads:

  if (not in store/load cache)
    {
      allocate store/load cache entry for load
      point store/load cache entry to value file entry of sourcing store
      if no sourcing store, insert result of load into value file
    }
  return value file entry as load result
```

Table I. Predictability of Store/Load Communication[a]

Benchmark	Instructions (millions)	Loads (millions)	Value locality	Address locality	Producer locality
go	548	157	25%	30%	43%
m88ksim	492	127	44%	28%	62%
gcc	264	97	32%	29%	53%
compress	3.5	1.3	15%	37%	50%
li	956	454	24%	23%	55%
perl	10	4.6	31%	24%	55%
intAVE	378	149	29%	29%	53%
tomcatv	2687	772	43%	48%	66%
su2cor	1034	331	29%	27%	68%
hydro2d	967	250	65%	25%	76%
mgrid	4422	1625	42%	30%	75%
fpAVE	2277	744	44%	32%	71%

[a] All programs were compiled with GNU GCC (version 2.6.2), GNU GAS (version 2.5), and GNU GLD (version 2.5) with maximum optimization (-O3) and loop unrolling enabled (-funroll-loops). The Fortran codes were first converted to C using AT&T F2C version 1994.09.27. All experiments were performed using the SimpleScalar[6] tool set.

The dependence predictor and its operation are detailed in Fig. 1. The predictor works by building bindings between loads and their most previous sourcing store. As shown in Table I, this approach to memory dependence prediction works quite well. In the table, the first three columns show the benchmark name, the total number of instructions executed and the total number of loads. The remaining columns show the predictability of various aspects of store/load communication, shown are the percent of time the load value, address, and sourcing store address does not change from the previous execution of the load.

A remarkable number of load instruction executions bring in the same values as the last time, averaging 29% for SPEC integer benchmarks and 44% for SPEC floating point benchmarks. While it is surprising that so much regularity exists in values, these percentages cover only about a third of all loads. For addresses, there is slightly more reuse. Finally, producer (or sourcing store) reuse is much higher—this means that the same store instruction generated the data for the load. Here we see that this relationship is far more stable—even when the values transferred change, or when a different memory location is used for the transfer. This observation led us to the use of dependence pairings between store and load instructions to identify when speculation would be most profitable.

Figure 1b details the operation of the memory renamer. When stores are executed, the memory dependence predictor is indexed with the PC of

the store to locate its entry in the array. If the store is not in the memory dependence predictor, it is inserted into the array. An entry in the value file is also allocated and its index is inserted into the store's entry in the memory dependence predictor. Entries in the value file are allocated using LRU, random, or another suitable strategy. Any newly allocated value file entry, however, should be one that is unlikely to be used in the near future. Finally, the store data, when available, is deposited into the value file entry associated with the store.

On a load instruction, the memory dependence predictor is indexed with the PC of the load to locate its entry in the array. If the load is not in the predictor, an entry is allocated, and the value file index of the load's sourcing store is inserted into the newly allocated entry. There are a number of approaches to identifying the value file entry of the sourcing store, ranging from tagging data storage with its value file entry index (the approach used in our experiments) to propagating value file indices through the store forwarding mechanism. Finally, the value file entry associated with the load is speculatively returned as the value of the load.

If a load instruction has no apparent sourcing store, e.g., it is a load of a constant or an infrequently stored variable, the result of the load from memory is inserted into the value file as well. This simple modification of the algorithm permits the memory renamer to act as a value predictor[4] for loads with no apparent sourcing store.

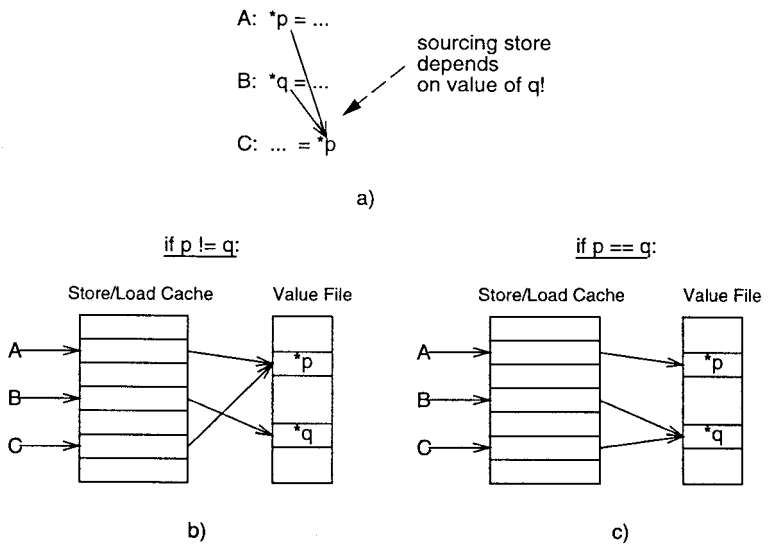

Fig. 2. Memory renaming example.

Figure 2 illustrates the memory renamer working for a small C code example. In this example, two stores at program address A and B could potentially source the load at program address C, depending on the value of *q*. We chose this example because it illustrates one of the harder problems in compiler register allocation that the memory renamer handles quite effortlessly. If the value of *p* is not equal to *q*, as in Fig. 2b), the renamer will map the definition of **p* and the use of **p* to the same value file entry. If, however, *p* is equal to *q*, as in Fig. 2c), the renamer will map the definition of **q* and the use of **p* to the same value file entry.

3. EXPERIMENTAL PIPELINE DESIGN

To support memory renaming, the pipeline must be extended to identify store/load communication pairs, promote their communications to the register communication infrastructure, verify speculatively forwarded values, and recover the pipeline if the speculative store/load forward was unsuccessful. In the following text, we detail the enhancements made to a baseline out-of-order issue processor pipeline. An overview of the extensions to the processor pipeline and load/store queue entries is shown in Fig. 3.

3.1. Promoting Memory Communication to Registers

The memory dependence predictor is integrated into the front end of the processor pipeline. During decode, the memory dependence predictor is probed (for both stores and loads) for the index of the value file entry assigned to the memory dependence edge. If the access hits in the memory dependence predictor, the value file index returned is propagated to the rename stage. Otherwise, an entry is allocated in the predictor and value file for the instruction. In addition, the decode stage may hold confidence counters[5] for renamed loads. These counters are incremented for loads when their sourcing stores are predicted correctly, and decremented (or reset) when they are predicted incorrectly. When a load reaches a predefined threshold, it is allowed to speculate. These counters are used to limit the cost of potentially expensive mis-peculation recoveries at the cost of some performance when correct predictions are not renamed.

In the rename stage of the pipeline, loads use the value file index, passed in from the decode stage, to access an entry in the value file. The value file returns either the value last stored into the predicted dependence edge, or if the value is in the process of being computed (i.e., in flight), a reservation station index is returned. If a reservation station index is returned, the load will stall until the sourcing store data is written to the store's reservation station. When a renamed load completes, it broadcasts

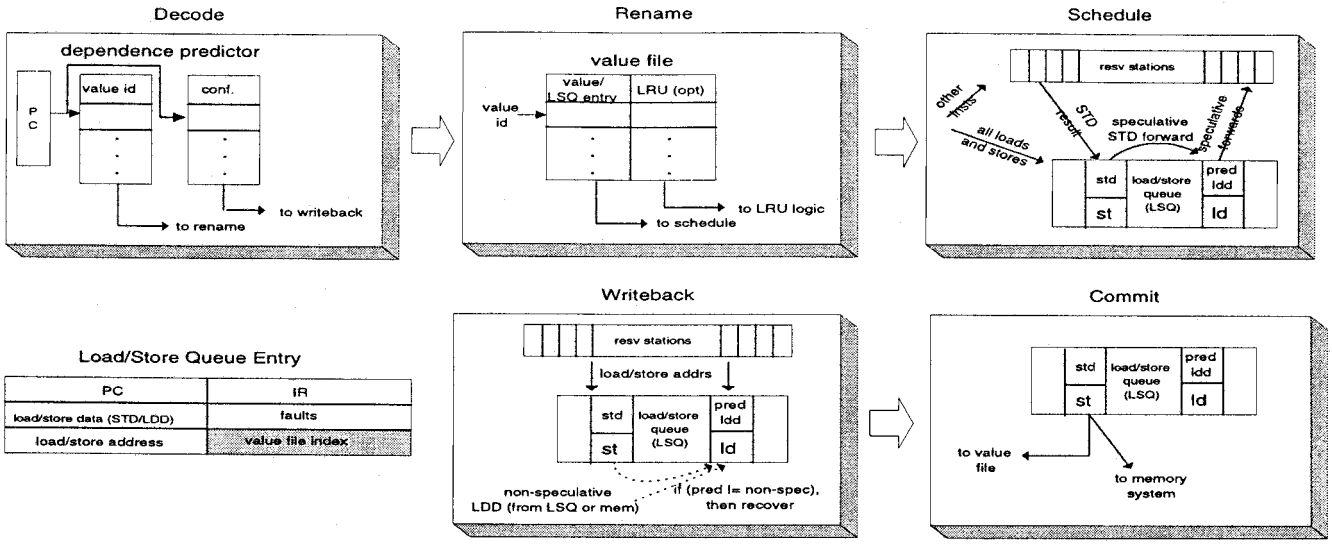

Fig. 3. Pipeline support for memory renaming. Shown are the additions made to the baseline pipeline to support memory renaming. The solid edges in the *writeback* stage represent forwarding through the reservation stations, the dashed lines represent forwarding through the load/store queue. Also shown are the fields added (shown in gray) to the instruction re-order buffer entries. Fields labeled with STD and LTD hold store and load data, respectively.

its result to dependent instructions; the register and memory scheduler operate on the speculative load result as before without modification. When a renamed store completes, it replaces its reservation index in the value file with the value stored.

By allowing a value file entry to contain a reservation station reference, it becomes possible to correctly rename multiple live instances of the same communication edge. To illustrate this case, consider the example from Fig. 2a) with the code embedded in a tight loop. If value file entries only contained values, the correct forwarding of store values to loads would require that all iterations of the loop execute without interleaving. If this were not the case, a load could see the store from another iteration of the loop, depending on the ordering of stores and loads. By storing reservation station references, we can correctly handle this case. Each store that cannot execute immediately will insert a new reservation station index in the value file, and the next load referencing this store value will wait on that reservation station to produce its result—remember that at this stage of the pipeline instructions are still processed in-order. Each iteration will see the correct store from the same iteration and the stores and loads from different iterations can execute with any interleaving without affecting the correctness of the computation.

All loads, speculative or otherwise, access the memory system. When a renamed load's non-speculative value returns from the memory system, it is compared to the predicted value. If the values do not match, a load data mis-speculation has occurred and pipeline recovery is initiated.

Unlike loads, store instructions do not access the value file until retirement. At that time, stores deposit their store data into the value file (overwriting their reservation station index) and the memory system. Any later renamed loads that reference this value will be able to access it directly from the value file. No attempt is made to maintain coherence between the value file and main memory. If their contents diverge (due to, for example, external DMAs or memory coherence operations), the pipeline will continue to operate correctly. Any incoherence will be detected when the renamed load values are compared to the actual memory contents.

The initial binding between stores and loads is created when a load that was not renamed references the data produced by a renamed store. We explored two approaches to detecting these new dependence edges. The simplest approach looks for renamed stores that forward to loads in the load/store queue forwarding network (i.e., communications between instructions in flight). When these edges are detected, the memory dependence predictor is updated accordingly. A slightly more capable approach is to attach value file indices to renamed store data, and propagate these indices into the memory hierarchy. This approach performs better because it can

detect longer-lived dependence edges, however, the extra storage for value file indices makes the approach more expensive.

3.2. Recovering from Mis-speculations

When a renamed load injects an incorrect value into the program computation, correct program execution requires that, minimally, all instructions that used the incorrect value and dependent instructions be re-executed. To this end, we explored two approaches to recovering the pipeline from data mis-speculations: *squash* and *re-execution* recovery. The two approaches exhibit varying performance degradation on a mis-speculation as well as differing implementation complexity.

Squash recovery, while expensive, is the simplest approach to implement. The approach works by throwing away all instructions after a mis-speculated load instruction. Since all dependent instructions will follow the load instruction, the restriction that all dependent instructions be re-executed will indeed be met. Unfortunately, this approach can throw away many instructions independent of the mis-speculated load result, requiring many unnecessary re-executions. The advantage of this approach is that it requires very little support over what is implemented today. Mis-speculated loads may be treated the same as mis-speculated branches.

Re-execution recovery, while more complex, has significantly better recovery performance than squash recovery. The approach leverages dependence information stored in the reservation stations of not-yet retired instructions to permit re-execution of only those instructions dependent on a speculative load value. The cost of this approach is added pipeline complexity.

We implemented re-execution by injecting the correct result of mis-speculated loads onto the result bus—all dependent instructions receiving the correct load result will re-execute, and re-broadcast their results, forcing dependent instructions to re-execute, and so on. Since it's non-trivial for an instruction to know how many of its operands will be re-generated through re-execution, an instruction may possibly re-execute multiple times, once for every re-generated operand that arrives. In addition, dependencies through memory may require load instructions to re-execute. To accommodate these dependencies, the load/store queue also re-checks memory dependencies of any stores that re-execute, re-issuing any dependent load instructions. Additionally, loads may be forced to re-execute if they receive a new address via instruction re-execution. At retirement, any re-executed instruction will be the oldest instruction in the machine, thus it cannot receive any more re-generated values, and the instruction may be safely retired. In the following section, we will demonstrate through simulation

that re-execution is a much less expensive approach to implementing load mis-speculation recovery.

4. EXPERIMENTAL EVALUATION

We evaluated the merits of our memory renaming designs by extending a detailed timing simulator to support the proposed designs and by examining the performance of programs running on the extended simulator. We varied the confidence mechanism, mis-speculation recovery mechanism, and key system parameters to see what affect these parameters had on performance.

4.1. Methodology

Our baseline simulator is detailed in Table II. It is from the Simple Scalar simulation suite (simulator *sim-outorder*).[6] The simulator executes only user-level instructions, performing a detailed timing simulation of an 4-way superscalar microprocessor with two levels of instruction and data

Table II. Baseline Simulation Model

Fetch interface	fetches any 4 instructions in up to two cache blocks per cycle, separated by at most two branches
Instruction cache	32 k 2-way set-associative, 32 byte blocks, 6 cycle miss latency
Branch predictor	8 bit global history indexing a 4096 entry pattern history table (GAp Yeh and Patt[15]) with 2-bit saturating counters, 8 cycle misprediction penalty
Out-of-order issue	out-of-order issue of up to 8 operations per cycle, 256 entry re-order buffer, 128 entry
Mechanism	load/store queue, loads may execute when all prior store addresses are known
Architected registers	32 integer, 32 floating point
Functional units	8-integer ALU, 4-load/store units, 4-FP adders, 1-integer MULT/DIV, 1-FP MULT/DIV
Functional unit latency	integer ALU-1/1, load/store-2/1, integer MULT-3/1, integer DIV-12/12, FP adder-2/1
(total/issue)	FP MULT-4/1, FP DIV-12/12
Data cache	32 k 2-way set-associative, write-back, write-allocate, 32 byte blocks, 6 cycle miss latency four-ported, non-blocking interface, supporting one outstanding miss per physical register 256 k 4-way set-associative, unified L2 cache, 64 byte blocks, 32 cycle miss
Virtual memory	4 K byte pages, 30 cycle fixed TLB miss latency after earlier-issued instructions complete

cache memory. The simulator implements an out-of-order issue execution model. Simulation is execution-driven, including execution down any speculative path until the detection of a fault, TLB miss, or misprediction. The model employs a 256 entry re-order buffer that implements renamed register storage and holds results of pending instructions. Loads and stores are placed into a 128 entry load/store queue. In the baseline simulator, stores execute when all operands are ready; their values, if speculative, are placed into the load/store queue. Loads may execute when all prior store addresses have been computed; their values come from a matching earlier store in the store queue (i.e., a store forward) or from the data cache. Speculative loads may initiate cache misses if the address hits in the TLB. If the load is subsequently squashed, the cache miss will still complete. However, speculative TLB misses are not permitted. That is, if a speculative cache access misses in the TLB, instruction dispatch is stalled until the instruction that detected the TLB miss is squashed or committed. Each cycle the re-order buffer issues up to 8 ready instructions, and commits up to 8 results in-order to the architected register file. When stores are committed, the store value is written into the data cache. The data cache modeled is a four-ported 32k two-way set-associative nonblocking cache.

We found early on that instruction fetch bandwidth was a critical performance bottleneck. To mitigate this problem, we implemented a limited variant of the collapsing buffer described by Conte *et al.*[7] Our implementation supports two predictions per cycle within the same instruction cache block, which provides significantly more instruction fetch bandwidth and better pipeline resource utilization.

When selecting benchmarks, we looked for programs with varying memory system performance, i.e., programs with large and small data sets as well as high and low reference locality. We analyzed 10 programs from the SPEC'95 benchmark suite, 6 from the integer codes and 4 from the floating point suite.

All memory renaming experiments were performed with a 1024 entry, 2-way set associative memory dependence predictor and a 512 entry value file with LRU replacement. To detect initial dependence edge bindings, we propagate the value file indices of renamed store data into the top-level data cache. When loads (that were not renamed) access renamed store data, the value file index stored in the data cache is used to update the load's entry in the memory dependence predictor.

4.2. Predictor Performance

Figure 4 shows the performance of the memory dependence predictor. The graph shows the hit rate of the memory dependence predictor for each

benchmark, where the hit rate is computed as the number of loads whose sourcing store *value* was correctly identified after probing the value file. The predictor works quite well, predicting correctly as many as 76% of the program's memory dependencies—an average of 62% for all the programs. Unlike many of the value predictor mechanisms,[4] dependence predictors work well, even better, on floating point programs.

To better understand where the dependence predictor was finding its dependence locality, we broke down the correct predictions by the segment in which the reference data resided. Figure 5 shows the breakdown of correct predictions for data residing in the global, stack, and heap segments. A large fraction of the correct dependence predictions, as much as 70% for Mgrid and 41% overall on the average, came from stack references. This result is not surprising considering the frequency of stack segment references and their semi-static nature, i.e., loads and stores to the stack often reference the same variable many times. (Later we leverage this property to improve the performance of the confidence mechanisms.) Global accesses also account for many of the correct predictions, as much as 86% for Tomcatv and 43% overall on the average. Finally, a significant number of correct predictions come from the heap segment, as much as 40% for Go and 15% overall on the average. To better understand what aspects of the program resulted in these correct predictions, we profiled top loads and then examined their sourcing stores, we found a number of common cases where heap accesses exhibited dependence locality[2]:

- repeated accesses to aliased data, which cannot be allocated to registers
- accesses to loop data with a loop dependence distance of one[3]
- accesses to single-instance dynamic storage, e.g., a variable allocated at the beginning of the program, pointed to by a few, immutable global pointers

As discussed in Section 3, a pipeline implementation can also benefit from a confidence mechanism. Figure 6 shows the results of experiments

[2] These examples are typical of program constructs that challenge even the most sophisticated register allocators. As a result, only significant advances in compiler technology will eliminate these memory accesses. The same assertion holds for global accesses, all of which the compiler must assume are aliased. Stack accesses on the other hand, can be effectively register allocated, thereby eliminating the memory accesses, given that the processor has enough registers.

[3] Note that since we always predict the sourcing store to be that last previous one, our predictors will not work with loop dependence distances greater than one, even if they are regular accesses. Support for these cases are currently under investigation.

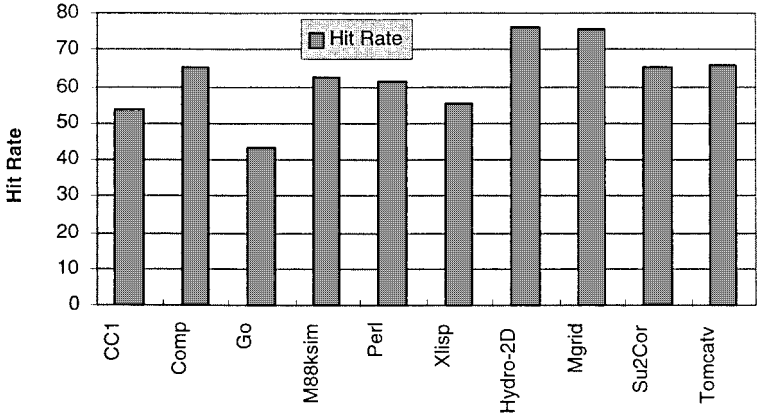

Fig. 4. Memory dependence predictor performance.

exploring the efficacy of attaching confidence counters to load instructions. The graphs show the confidence and coverage for a number of predictors. *Confidence* is the success rate of high-confidence loads. *Coverage* is the fraction of correctly predicted loads, without confidence, covered by the high-confidence predictions of a particular predictor. Confidence and coverage are shown for 6 predictors. The notation used for each is as follows: XYZ, where X is the count that must be reached before the predictor considers the load a high-confidence load. By default, the count is incremented by one when the predictor correctly predicts the sourcing store value, and

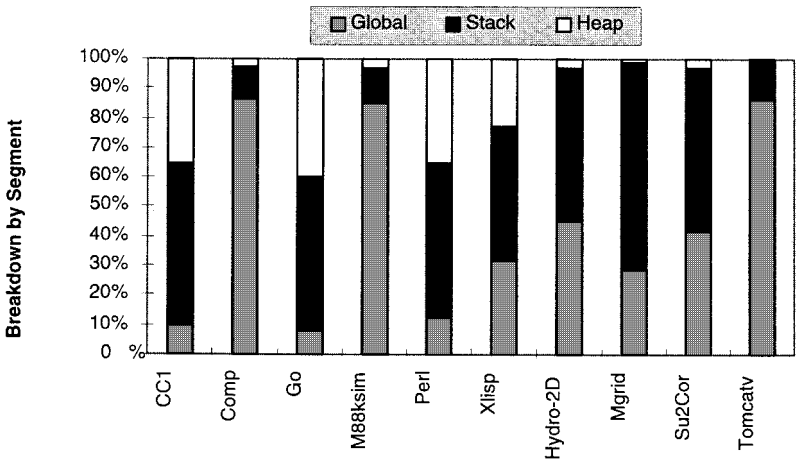

Fig. 5. Predictor hits by memory segment.

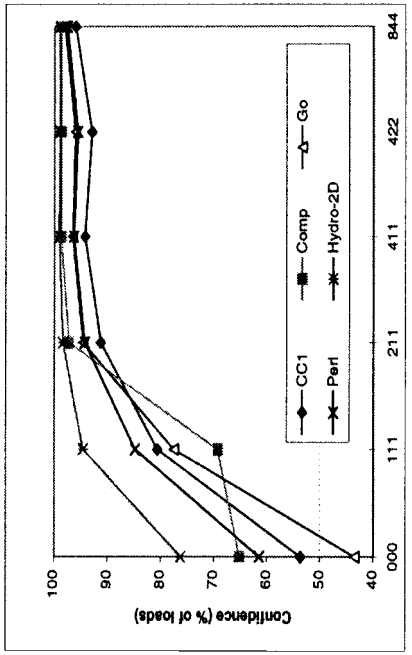

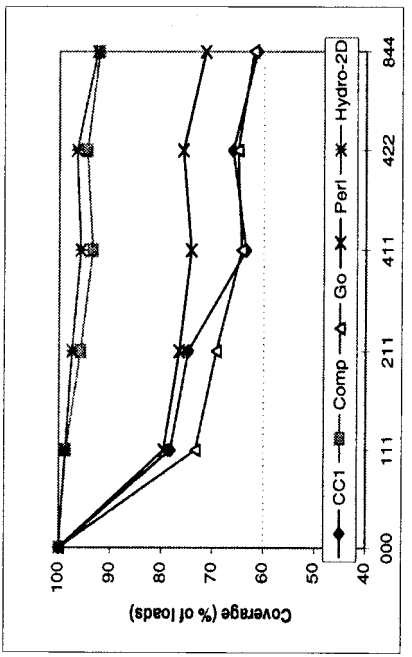

Fig. 6. Confidence and coverage for predictors with confidence counters.

reset to zero when the predictor fails. Y is the count increment used when the opcode of the load indicates an access off the stack pointer. Z is the count increment used when the opcode of the load indicates an access off the global pointer. Our analyses showed that stack and global accesses are well behaved, thus we can increase coverage, without sacrificing much confidence, by incrementing their confidence counters with a value greater than one.

As shown in Fig. 6, confidence is very high for the configurations examined, as much as 99.02% for Hydro-2D and at least 69.22% for all experiments that use confidence mechanisms. For most of the experiments we tried, increasing the increments for stack and global accesses to half the confidence counter performed best. While this configuration usually degrades confidence over the baseline case (an increment of one for all accesses), coverage is improved enough to improve program performance. Coverage varies significantly, a number of the programs, e.g., Compress and Hydro-2D, have very high coverage, while others, such as CC1 and Perl do not gain higher coverage until a significant amount of confidence is sacrificed. Another interesting feature of our confidence measurements is the relative insensitivity of coverage to the counter threshold once the confidence thresholds levels rise above 2. This reinforces our earlier observation that the memory dependencies in a program are relatively static—once they occur a few times, they very often occur in the same fashion for much of the program execution.

4.3. Pipeline Performance

Predictor hit rates are an insufficient tool for evaluating the usefulness of a memory dependence predictor. In order to fully evaluate it, we must integrate it into a modern processor pipeline, leverage the predictions it produces, and correctly handle the cases when the predictor fails. Figure 7 details the performance of the memory dependence predictor integrated into the baseline out-of-order issue performance simulator. For each experiment, Fig. 7 shows the speedup (in percent, measured in cycles to execute the entire program) with respect to the baseline simulator.

Four experiments are shown for each benchmark in Fig. 7. The first experiment, labeled SQ-422, shows the speedup found with a dependence predictor utilizing a 422 confidence configuration and squash recovery for load mis-speculations. Experiment SQ-844 is the same experiment except with a 844 confidence mechanism. The RE-422 configuration employs a 422 confidence configuration and utilizes the re-execution mechanism described in Section 2 to recover from load mis-speculations. Finally, the

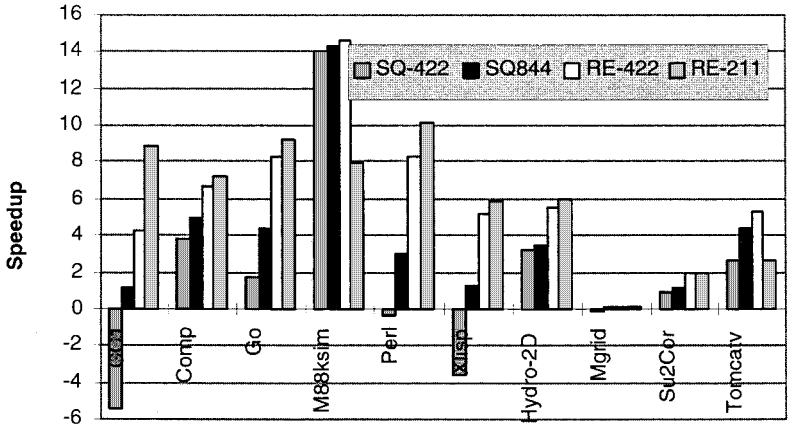

Fig. 7. Program performance with varied predictor/recovery configuration.

RE-211 configuration also employs the re-execution recovery mechanism, but utilizes a lower-confidence 211 confidence configuration.

The configuration with squash recovery and the 422 confidence mechanism, i.e., SQ-422, shows small speedups for many of the programs, and falls short on others, such as CC1 which saw a slowdown of more than 5%. Investigation of these slowdowns quickly revealed that the high-cost of squash recovery, i.e., throwing away all instructions after the mis-speculated load, often completely outweighs the benefits of memory renaming. (Many of the programs had more data mis-speculations than branch mispredictions!) One remedy to the high-cost of mis-speculation is to permit renaming only for higher confidence loads. The experiment labeled SQ-844 renames higher-confidence loads. This configuration performs better because it suffers from less mis-speculation, however, some experiments, e.g., CC1, show very little speedup because they are still plagued with many high-cost load mis-speculations.

A better remedy for high mis-speculation recovery costs is a lower cost mis-speculation recovery mechanism. The experiment labeled RE-422 adds re-execution support to a pipeline with memory renaming support with a 422 confidence mechanism. This design has lower mis-speculation costs, allowing it to to show speedups for all the experiments run, as much as 14% for M88ksim and an average overall speedup of over 6%. To confirm our intuitions as to the lower cost of re-execution, we measured directly the cost of squash recovery and re-execution for all runs by counting the number of instructions thrown away due to load mis-speculations. We found that overall, re-execution consumes less than 1/3 of the execution bandwidth required by squash recovery—in other words, less than 1/3 of the

instructions in flight after a load mis-speculation are dependent on the mis-speculated load, on average. Additionally, re-execution benefits from not having to re-fetch, decode, and issue instructions after the mis-speculated load.

Given the lower cost of cost of re-execution, we explored whether speedups would be improved if we also renamed lower-confidence loads. The experiment labeled RE-211 employs re-execution recovery with a lower-confidence 211 confidence configuration. This configuration found better performance for most of the experiments, further supporting the benefits of re-execution. We also explored the use of yet even lower-confidence (111) and no-confidence (000) configurations, however, mis-speculation rates rise quickly for these configurations, and performance suffered accordingly for most experiments.

Figure 8 takes our best-performing configuration, i.e., RE-211, and varies two key system parameters to see their effect on the efficacy of memory renaming. The first experiment, labeled FE/2, cuts the peak instruction delivery bandwidth of the fetch stage in half. This configuration can only deliver up to four instructions from one basic block per cycle. For many of the experiments, this cuts the average instruction delivery bandwidth by nearly half. As shown in the results, the effects of memory renaming are severely attenuated. With half of the instruction delivery bandwidth the machine becomes fetch bottle-necked for many of the experiments. Once fetch bottle-necked, improving execution performance with memory renaming does little to improve the performance of the program. This is especially true for the integer codes where fetch bandwidth is very limited due to many small basic blocks.

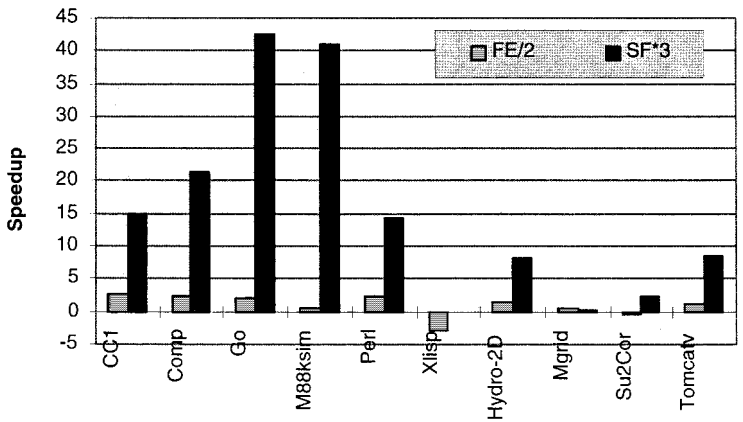

Fig. 8. Program performance with varied system configuration.

The second experiment in Fig. 8, labeled SF*3, increases the store forward latency three-fold to three cycles. The store forward latency is the minimum latency, in cycles, between any two operations that communicate a value to each other through memory. In the baseline experiments of Fig. 7, the minimum store forward latency is one cycle. As shown in the graph, performance improvements due to renaming rise sharply, to as much as 42.5% for go and more than 16% overall. This sharp rise is due to the increased latency for communicate through memory—this latency must be tolerated, which consumes precious parallelism. Renamed memory accesses, however, may communication through the register file in potentially zero cycles (via bypass), resulting in significantly lower communication latencies. Given the complexity of load/store queue dataflow analysis and the requirement that it be performed in one cycle for one-cycle store forwards (since addresses in the computation may arrive in the previous cycle), designers may soon resort to larger load/store queues with longer latency store forwards. This trend will make memory renaming more attractive.

A fitting conclusion to our evaluation is to grade ourselves against the goal set forth in the beginning of this paper: build a renaming mechanism that maps all memory communication to the register communication and synchronization infrastructure. It is through this hoisting of the memory communication into the registers that permits more accurate and faster memory communication. To see how successful we were at this goal, we measured the breakdown of communication handled by the load/store queue and the data cache. Memory communications handled by the load/store queue are handled "in flight", thus this communication can benefit from renaming. How did we do? Figure 9 shows for each benchmark, the fraction of references serviced by the load/store queue in the base configuration, labeled Base, and the fraction of the references serviced by the load/store queue in the pipeline with renaming support, labeled RE-422. As shown in Fig. 9, a significant amount of the communication is now being handled by the register communication infrastructure. Clearly, much of the short-term communication is able to benefit from the renamer support.

However, a number of the benchmarks, e.g., CC1, Xlisp, and Tomcatv, still have a nontrivial amount of short-term communication that was not identified by the dependence predictor. For these programs, the execution benefits were derived from the ability of the load/store queue to quickly compute load/store dependencies when addresses become available. One goal of this work is to improve the performance of the dependence predictor until virtually all short-term communication is captured in the high-confidence predictions. Not only will this continue to improve the performance of memory communication, but once this goal has been attained, the performance of the load/store queue will become less important to

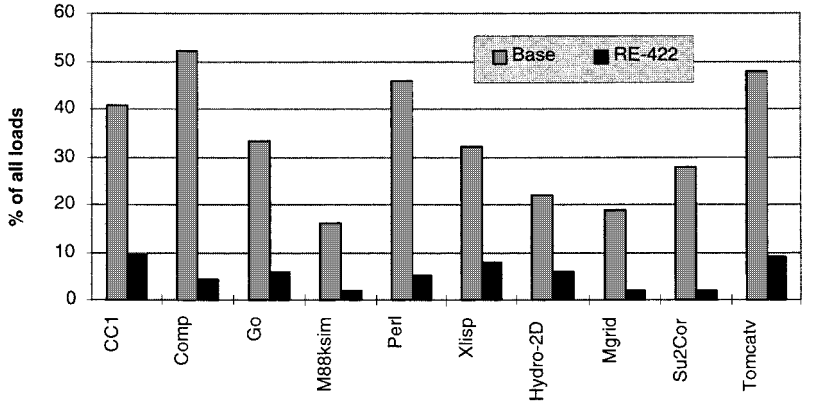

Fig. 9. Percent of memory dependencies serviced by load/store queue.

overall program performance. As a result, less resources will have to be devoted to load/store queue design and implementation.

5. RELATED WORK

A number of studies have targeted the reduction of memory latency. Austin and Sohi[8] employed a simple, fast address calculation early in the pipeline to effectively hide the memory latency. This was achieved by targeting the simple *base* + *offset* addressing modes used in references to global and stack data.

Dahl and O'Keefe[9] incorporated address bits associated with each register to provide a hardware mechanism to disambiguate memory references dynamically. This allowed the compiler to be more aggressive in placing frequently referenced data in the register file (even when aliasing may be present), which can dramatically reduce the number of memory operations that must be executed.

Lipasti *et al.*[4] described a mechanism in which the value of a load instruction is predicted based on the previous values loaded by that instruction. In their work, they used a *load value prediction unit* to hold the predicted value along with a *load classification table* for deciding whether the value is likely to be correct based on past performance of the predictor. They observed that a large number of load instructions are bringing in the same value time after time. By speculatively using the data value that was last loaded by this instruction before all dependencies are resolved, they are able to remove those dependencies from the critical path (when speculation was accurate). Using this approach they were able to achieve a speedup in

execution of between 3% (for a simple implementation) to 16% (with infinite resources and perfect prediction).

Sazeides *et al.*[10] used address speculation on load instructions to remove the dependency caused by the calculation of the effective address. This enables load instructions to proceed speculatively without their address operands when effective address computation for a particular load instruction remains constant (as in global variable references).

Finally, Moshovos *et al.*[3] used a memory reorder buffer incorporating data dependence speculation. Data dependence speculation allows load instructions to bypass preceding stores before ambiguous dependencies are resolved; this greatly increases the flexibility of the dynamic instruction scheduling to find memory instruction ready to execute. However, if the speculative bypass violates a true dependency between the load and store instructions in flight, the state of the machine must be restored to the point before the load instruction was mis-speculated and all instructions after the load must be aborted. To reduce the number of times a mis-speculation occurs, a prediction confidence circuit was included controlling when bypass was allowed. This confidence mechanism differs from that used in value prediction by locating dependencies between pairs of store and load instructions instead of basing the confidence on the history of the load instruction only. When reference prediction was added to the Multiscalar architecture, execution performance was improved by an average of 5–10%. Independently, Moshovos and Sohi[11] extended their earlier work to rename memory communication to fast physical storage, much like the work presented in this paper.

Our approach to speculation extends both value prediction and dependence prediction to perform targeted speculation of load instructions early in the architectural pipeline. Recent research has further extended the memory renaming techniques outlined in this paper.

Reinman, *et al.*[12] have explored the feasibility of replacing much of the hardware requirements for identifying stable store/load pairs with compile time analysis. They propose a software-guided approach for identifying dependencies between store and load instructions as well as a new Load Marking (LM) architecture to communicate these dependencies to the hardware. Compiler analysis and profiles are used to find stable store/load relationships, and these relationships are identified during execution via hints or an n-bit tag. For those loads that are not marked for renaming, additional profiling information is used to further classify the loads into those that have accurate value prediction and those that do not. These classifications allow the processor to individually apply the most appropriate aggressive form of execution for each load. Their results indicate that compile-time classification can mark an average of 30–40% of loads for

renaming with very high accuracy. The majority of the remaining loads can be classified as either value predicting or independent.

Jourdan *et al.*[13] propose a novel extension to both register renaming and memory renaming in which they integrate the value file into the physical register file. In this scheme, conventional register renaming circuitry is modified to enable mapping of multiple architected registers to the same physical register entry when those architected registers hold the same value. This can lead to a significant reduction in the number of physical registers needed to support aggressive out-of-order pipeline processing by eliminating duplicate values in the physical register file. The extra space is then used to store value file entries required by the memory renamer. This approach leads to a more efficient utilization of storage space by unifying the physical register file and the value file.

Reinman and Calder[14] examined the effectiveness of pipelines using various combinations of value, address, and dependence prediction. With performance simulation, they found that aggressive value predictors yielded the largest performance improvements, more than memory renaming for most programs. However, when value prediction and memory renaming were combined, the renamer could provide 9% more correct predictions than with the value predictor alone. In addition, they found that the high accuracy of the dependence predictor could be used to speed detection of value mispredictions. By applying dependence speculation techniques (such as memory renaming) to the non-speculative check load, it is possible to reduce the latency of misprediction detection. Of course, if the check load speculation is incorrect, it may force recovery of a correct value prediction, however, given the much higher accuracies of dependence prediction (compared to value prediction) this case happens infrequently enough to provide overall benefits.

6. CONCLUSIONS

In this paper we have described a new mechanism designed to improve memory performance. This was accomplished by restructuring the processor pipeline to incorporate a speculative value and dependence predictor to enable load instructions to proceed much earlier in the pipeline. We introduce a prediction confidence mechanism based on store-load dependence history to control speculation and a value file containing load and store data which can be efficiently accessed without performing complex address calculations. Simulation results validate this approach to improving memory performance, showing an average application speedup of 16%.

We intend to extend this study in a number of ways. The most obvious extension of this work is to identify new mechanisms to improve the

confidence mechanism and increase the applicability of this scheme to more load instructions. To do this we are exploring integrating control flow information into the confidence mechanism. Another architectural modification is to improve the efficiency of squashing instructions affected by a misprediction. This is starting to become important in branch prediction, but becomes more important in value prediction because of the lower confidence in this mechanism. Also, the number of instructions that are directly affected by a misprediction in a load value is less than for a branch prediction allowing greater benefit from a improvement in identifying only those instructions that need to be squashed.

ACKNOWLEDGMENTS

We would like to acknowledge the help of Haitham Akkary, who offered numerous suggestions which have greatly improved the quality of this work. We are also grateful to the Intel Corporation for its support of this research through the Intel Technology for Education 2000 grant.
